Dual: a web-based, Pac-Man-complete hybrid text and visual programming language

Praca magisterska
napisana pod kierunkiem
dr inż. Jana Stolarka

Łódź 2016

Contents

Chapter 0

Introduction

0.1 Title

The term "Pac-Man-complete" in the title refers to a somewhat humorous description of the Idris programming language[1] attributed to the language's author, Edwin Brady[2]. In the context of this thesis it means that the designed and implemented programming language is complete enough and provides enough features to allow one to write a clone of the classic Pac-Man game in it.

0.2 Scope

This research explores various topics in the field of programming language design. Particularly, the possibilities of integrating and combining multiple representations of the same programming language in a dynamic way. I try to find ways of combining features of visual languages with text-based languages by creating a development environment which lets the programmer work with both representations in parallel or intertwine them in any way.

The created language is used to implement a Pac-Man clone. This provides a demonstration of Dual's capabilities and is a reference for assessing the performance of the implementation.

I discuss further possible improvements in the language's design and performance, as well as set down directions for any future research, which I intend to take on. The exploratory nature of this work lets me cover a fairly broad area, connecting programming language design, computer game development as well as web technologies and web application development.

[2]`https://twitter.com/folone/status/494017847585415168`

0.3   Choice of subject

The choice of this particular subject stems from my deep personal interest in programming language design. This research is an opportunity for me to create a project that demonstrates various ideas in this area that I developed over time and to explore and refine them further.

0.4   Related work

Visual languages are not especially popular compared to text-based languages. But recently they have been gaining more popularity, particularly in game development. Chief example and the main cause of this is Unreal Engine, the highly popular and mainstream[3] game engine, which in the latest version introduced a visual programming language[4] as its primary scripting language. In fact this is the only scripting language that the engine supports, having dropped the UnrealScript language[5] included in the previous versions.

I intend to further the growth of visual programming languages, propose an even more accessible solution and explore possible improvements over comparable technologies.

I create a unique design, which combines [|||] and seems to be, certainly not to this extend and not with these technologies, a previously unexplored ground.

It's also a good text-based language designed with rapid prototyping of computer games and web applications in mind, but fairly applicable as a more general-purpose solution.

Not tied to any commercial product, dependent only on the ubiquitous web platform.

Furthermore ideas regarding programming language design presented here are applicable in general, regardless of technology.

0.5   Goals

In line with the above, the purpose of this work is to introduce innovation as well as show a practical application of the developed solution. The concrete goals are:

- Design and implement a programming language, whose *complete* textual representation must be directly and dynamically mappable to a visual representation and vice versa

- Explore and establish directions where innovation is possible in programming language design and implementation

---

[3]https://en.wikipedia.org/wiki/List_of_Unreal_Engine_games,   http://www.guinnessworldrecords.com/world-records/most-successful-game-engine

[5]http://www.gamasutra.com/view/news/213647/Epics_Tim_Sweeney_lays_out_the_case_for_Unreal_Engine_4.php

- Create a prototype of the development environment for the language on top of the web platform

- Evaluate the performance of the language by implementing a clone of Pac-Man and comparing it to other implementations

- Explore and discuss further refinements and possible future design directions

- Compare the language to existing solutions

0.6 Structure

This thesis is structured as follows:

Chapter 0 is this introduction.

Chapter 1 briefly describes technologies and tools used in developing any software described here.

Chapter 2 discusses the essential elements of the theoretical framework upon which the language was built.

Chapter 3 describes the Dual language: its syntax, semantics and basic design.

Chapter 4 talks about the architecture, design and serves as a practical documentation of the language editor and visual representation.

Chapter 6 elaborates on language design both in context of Dual and in general.

Chapter 5 describes a non-trivial application developed with Dual: a Pac-Man clone. Performance of the language is assessed [[compared]] and possible adjustments and improvements are discussed.

Chapter 7 relates the language with other similar solution, [[Unreal Engine's Blueprint]].

Chapter 8 summarizes and concludes.

Czy rozwiązania istniejące w danej dziedzinie nie są wystarczające? Czy problem można rozwiązać inaczej? Czy podejmowany problem jest aktywnym tematem badawczym? Przed jakimi wyzwaniami stoi osoba podejmująca tematykę? Na tym etapie należy zarysować problem w sposób ogólny.

Cele muszą być sformułowane w sposób zwięzły i **ścisły**.

Alternatywnie, zamiast zakładać tutaj cele do realizacji, można opisywać wkład pracy dyplomowej w stan wiedzy w danej dziedzinie. W ten sposób czytelnik już na wstępie wie, jakie są osiągnięcia autora.

W tym podrozdziale należy szczegółowo uzasadnić dlaczego wybrany został taki a nie inny temat pracy. Trzeba przede wszystkim zaprezentować aktualny stan wiedzy w danej dziedzinie. Oznacza to konieczność omówienia książek (ew. artykułów naukowych bądź dokumentacji technicznej) z których będzie się korzystać w trakcie rozprawy. Następnie należy wskazać – tym razem już konkretnie – co nowego zamierza się zrobić. Podstawowymi celami tego podrozdziału jest wprowadzenie czytelnika w aktualny stand danej dziedziny i przekonanie go że **naprawdę warto zajmować się podjętym tematem**.

Chapter 1

Tools and methods

This chapter briefly introduces the theoretical and practical components involved in design and implementation of the Dual programming language and its environment. I may further use the terms "Dual system" or simply "system" to refer to these.

1.1   Web technologies

One of the main goals in designing the system is accessibility. This is accomplished in practice by building it on top of arguably the most accessible and ubiquitous platform – the web platform[1].

The language's interpreter and development environment is intended to work with and is built on web technologies. Specifically JavaScript, HTML5 and CSS. The prototype implementation makes use of Node.js – server-side JavaScript runtime and CodeMirror[2] – a JavaScript library which provides basic facilities for the text-based code editor part of the system. This part is modeled after modern web-oriented code editors with similar design philosophy[3], such as Visual Studio Code[4], Brackets[5], Atom[6] and many others.

The design of Dual's visual representation draws from many visual programming languages[7]. Analyzing these, we can observe many distinct approaches of which two particular designs are the most widespread and successful. These can be described as line-connected block-based and snap-together block-based visual languages. The former family is exemplified by the Blueprints Visual Scripting

system of Unreal Engine 4[8] and the latter by MIT Scratch[9].

1.2   Programming languages

1.3   Programming discipline

The prototype was implemented largely in the spirit of exploratory programming: "the kind where you decide what to write by writing it."[10].

This approach in combination with a dynamic and flexible language like JavaScript enables one to quickly transform ideas to working prototypes and shape them as one goes along. But the usefulness of this method is limited, as it may quickly produce fairly low-quality code, as it is not focused on future maintainability.

An example application built with the language

Canvas element

Other related technologies that are relevant to development of the language are:

- JavaScript components that provide code editor features, specifically CodeMirror, which is used as the text editor component component of the Dual programming language editor

- Standalone modern code editors, built with web technologies and with web development in mind, such as:

    - Visual Studio Code[11]
    - Brackets[12]
    - Atom[13]

- Node.js[14], a JavaScript-based runtime environment for developing server-side web applications

introduce arity notation 0..* 0..2 2 etc.

functional purity and why not

2.2 Web platform

2.2.1 JavaScript

WebAssembly?

Programming languages build on top of each other and cross over to form complex taxonomies.

My most recent and significant experience both professional and non-professional is with the JavaScript language.

I find this language well-suited to a great range of tasks []

JavaScript has many great design features, borrowed from other excellent languages and packaged in a familiar syntax. For this reason and because it is distributed with a ubiquitous environment, which is the web browser, it became one

of the most[1], if not the most[2] popular programming lanugages in the world.

The popularity of JavaScript grew over time[3]

EcmaScript 2015 Now 2016

https://en.wikipedia.org/wiki/Measuring_programming_language_popularity

In my design I

Concurrency model

In the context of the concurrency model, the JavaScript runtime conceptually consists of three parts: the call stack, the heap and the message queue. All these are bound together by the event loop[4], which is the crucial part of this model. An iteration of this loop involves the following steps:

1. Take the next message from the queue or wait for one to arrive. At this point the call stack is empty.

2. Start processing the message by calling a function associated with it. Every message has an associated function. This initializes the call stack.

3. Processing stops when the stack becomes empty again, thus completing the iteration.

This means[5] that messages are processed one by one, in a single thread and an executing function cannot be preempted by any other function before it completes.

This model makes reasoning about the program execution very straightforward, but is problematic when a single message takes long to execute. This problem is observed in practice when web applications cause browsers to hang or display a dialog asking the user if he wishes to terminate an unresponsive script.

For this reason it is best to write programs in JavaScript that block the event loop for as short as possible and divide the processing into more messages.

The mechanism is called the *event* loop, because the messages are added to the queue any time an event occurs (an has an associated handler), such as a click or a scroll. In general input and output in JavaScript is performed asynchronously, through events, so it does not block program execution.

[3]http://www.r-bloggers.com/the-most-popular-programming-languages-on-stackoverflow/

[4]https://developer.mozilla.org/en-US/docs/Web/JavaScript/EventLoop

[5]At least conceptually. In practice it is much more complicated and there are exceptions to these rules. But this explanation is sufficient for further discussion.

2.3 Programming language design

2.3.1 Syntax

"It's surprising that you can write in a language without using its syntax. Usually when we're reviewing languages syntax is all we look at. We look at the most superficial aspect of it. And often it could be years before we discover what's in the deeper layers." – Douglas Crockford, https://www.youtube.com/watch?v=Nlqv6NtBXcA 4:00

JavaScript design time: 10 days Smalltalk design time: 10 years

2.4 Abstract syntax tree

Visual programming is essentially manipulating a visual form of the syntax tree.

Visual Programming Language

2.5 Visual programming language

This section means of research, that are rather heuristic in nature and not formal provide a starting point and a reference for design

A formal study of visual programming languages, proper classification in terms of statistics and methodical examination are not the focus of this thesis.

The design of the visual representation involved a rough survey of visual programming languages[6]

I classified each of nearly 160 languages, according to type of their visual representation, to one of three categories:

1. Line-connected blocks: about 66%

2. Snap-together blocks

3. Other

Additionally, I associated each language with a number $s \in [0, 3]$, which descirbes its "structure factor". This tries to quantify my subjective assessment of the readability of the representation compared to familiar text representation $(s = 3)$[7].

Below I present the results of this classification. The elements are structured as follows: name of category – percentage of languages that fall into the category – the average "structure factor" s for the category This yielded the following results:

1. Arrow/line connected blocks – 66% – 0.61

---

[6]http://blog.interfacevision.com/design/design-visual-progarmming-languages-snapshots/

[7]This is based solely on the screen shots from the editors. For example, if it appears that the representation consists of scattered blocks, connected by lines and the layout seems to be arranged by the user, with no automatic structuring by the editor, s will be low.

2. Snap-together blocks – 11% – 2.4

3. Other representations – 23% – 1.39, notably:

    (a) Lists – 2.5% – 2

    (b) GUI – 2.5% – 1

    (c) Nested – 2.5% – 2

    (d) Enhanced text – 2.5% – 2.75

    (e) Timeline – 2% – 1.17

    (f) *The remaining 11% are various other representations: in-game VPLs, hybrid, specialized, esoteric, etc.*

Taking into account the above and looking at the most popular visual programming languages[8]

From this and a I drew the conclusion that there are basically two main representations. A flowchart-like representation, exemplified by the Blueprints, with blocks connected by lines or arrows, which usually leaves the layout of the program source completely to the user, providing no automatic structuring. Another representation is exemplified by MIT Scratch. There, the code is represented and manipulated in terms of snap-together blocks, similarly to a jigsaw-puzzle. This representation is self-structuring and is designed to resemble a faimiliar text-based, indent-structured representations.

The advantages of the first representation is that it clearly separates

The lack of support for automatic structuring, which is an essential feature of modern text-based code editors is obviously a regression.

---

[8]I was not able to find and am not aware of any official or even unofficial ranking of popularity of visual programming languages, but analyzing the top hits when google searching the phrase "visual programming language" in combination with `https://en.wikipedia.org/wiki/Visual_programming_language` and my personal experience suggest that we can find these among the most popular: MIT Scratch Unreal Engine 4's Blueprints

Chapter 3

Dual programming language

Jeśli w ramach pracy autor rozwinął nową teorię należy zamieścić ją w tym rozdziale.

3.1 Introduction

I recognize that the textual representation is very useful and will be used by programmers if available. Any text editor Quick fix ...

First prototype

iterations

background: BNF? just mention?

Advantages of a textual representation: Find and replace Block editing Flexibility Quick editing

In order to make a visual language a viable choice for textual-oriented programmer it's important that a language has a solid textual representation.

This chapter describes the textual representation of Dual, which is the basis for the executable representation for the interpreter (the syntax tree) and for any other editable representation – including the block-based visual representation implemented in the prototype.

While implementing this project I learned that programming language design is a tremendous task, especially if the language being designed is intended to be of real-world use. Designing and implementing such a language absolutely from scratch, while introducing useful innovation cannot be done within the time limits of research for a thesis, unless perhaps by an experienced language designer. But such experience has to be gained somehow and this is an excellent opportunity.

The character of this research project is exploratory, although I intend to further develop ideas described here and continue my research, which will, as I hope, eventually result in creation of an innovative and useful language ready for real-world use.

That aside, I believe that at least some of the ideas described here are – in a varying degree – innovative and worth exploring further.

The evolution of programming languages is a gradual process. And so is the process of designing a single language. The approach that I found effective was

iterative refinement, addition, testing, and sometimes subtraction of features. In practice this translates to intermediate designs and implementations being rearranged into new forms, with some discarded. I did not arrive at something that I could call the final form of the language, so a lot of the features described here are subject to change and improvement. This might show in descriptions, where along with talking about the prototype implementation I propose alternatives and refinements.

In chapter [|||] I discuss features and ideas that reached only the design stage and were not implemented, although some of them will be further researched outside of scope of this thesis.

Most of the features of the language and editor in the prototype are implemented as a proof-of-concept, although some are more refined than others in order to fulfill the major goals of this thesis, one of which was to implement a working non-trivial application in the language. I cover a lot of design and implementation surface, only delving deep into some features that are relevant to core ideas that I wanted to convey in this thesis. The other features are implemented necessarily, as steps along the path to practical application of those ideas.

For these reasons the created environment is by no means complete and ready for use in developing complex applications. The degree of completeness of the project is reflected in:

- The core language, which is sufficiently expressive to implement any algorithm, i.e. Turing-complete in the practical sense[1]. A simple Brainfuck[2] interpreter is included as an example program [[resources]] to demonstrate this

- Implementation of several interesting additional features of the core language, which are described in this chapter

- The ablility of the language to implement also non-trivial applications. This is demonstrated by implementing a clone of Pac-Man, described in Chapter 5

- The direct correspondence of the visual and text representations, with the possibility of parallel dynamic editing; albeit the visual editing part of the editor includes only basic features and is not optimized in terms of performance; details are described in Chapter 4

- Implementation of the prototype of the language's development environment on top of the web platform, which includes a server-side and a client-side part. It runs locally on the user's machine, but is designed to be easily deployed as an online web application

---

[1]That is, it is as Turing-complete as JavaScript or C. No existing language is really Turing-complete in the absolute sense, because of physical hardware limitations.

[2]Which is easily demostrable to be Turing-complete: `http://www.iwriteiam.nl/Ha_bf_Turing.html` and thus

- The editor has several useful features, such as basic support for text editing built on top of the CodeMirror JavaScript component with custom syntax highlighting and integration with the editor. The text editing component is integrated with the visual editing component, so that navigation or changes to each representation are tracked and visible to the user [[[]

[ ]

The Pac-Man clone is implemented in a stable subset of the language [[[]

The language was not originally intended as a Lisp-like language of clone thereof, but throughout the research I ended up reinventing some language constructs characteristic of Lisp and learning a lot of and about the language.

An somewhat philosophical interpretation of this would be that Lisp is built on some fundamental principles that are (re)discoverable rather than invented.

It seems that if we reduce a design of a programming language design to its essentials, we are left with Lisp. Such essentials are:

- Syntax. Lisp has a very minimal syntax that is built on the principle of Any scope is marked with a beginning and an end symbol. Operators are recognized by their position in the source. If we exclude various extensions, flavors and modifications, there's no extraneous characters or symbols

- Definitions, declarations

- Eval & apply

Even though the language presented in this thesis is complete in the sense of being able to implement any algorithm and non-trivial applications, as exemplified by the Pac-Man clone, it is by no means a complete design. It should be viewed as a snapshot from a continuous design process that is intended to progress in the future.

Provided brief specification and description primarily describes the implementation provided with this thesis. But it is also annotated with suggestions for improvements or, in other words, descriptions of the more refined, future design, which itself is subject to change.

3.2   Name

The name of the language reflects the original core concept of the two concurrent representations: the visual and text. Throughout this research however, I was able [[[] to generalize the concept to any number of possible representations.

But duality is present in many aspects of the language [[see definition/evaluation duality, chap:design]] and in a more general, philosophical sense it's a fundamental principle of reality. The language is something of an exploration of this and other fundamental principles, if not of reality, then at least of programming language design. So, since "Basic" is already taken and "Fundamental" sounds somewhat pejorative, I stuck with the original name. :D

3.3 Grammar and syntactic features

Among the main design goals for the prototype of the language were simplicity and clarity. I wanted a language that is easy to parse and transform to a different representation. This restriction suggests that the syntax should be as minimal as possible. A language with one of the most (if not *the* most) minimal syntax is Lisp[?].

An interpreter for List is also trivial to implement, so this is a good starting point.

There are many approaches to implementing interpreters for LISP in JavaScript[3], but the general principles are the same.

Although I opted for a minimal syntax, I did not want it to be exactly Lisp-like, as I thought the syntax of this language could be considerably improved – in terms of ease of use and parsing by a human – with a few simple adjustments, without significantly increasing the complexity of the interpreter.

There primary criticisms of Lisp's syntax are:

- Almost absolute uniformity of syntax makes the source code difficult to read by a human and thus [|||

- In general it is hard to teach[?], because complex code gets easily confusing

- The more nested the syntax tree, the harder it is to keep track of and balance parentheses; there tends to be a lot of closing parentheses next to each other in the source[4]

3.3.1 Basic syntax

Before the primary notation of Lisp, namely S-expressions[5], was established – a slightly different and, in my opinion, slightly more readable notation was used in the early theoretical publications about the language, called meta-expressions or M-expressions[?]. I first simplified this notation in the following way:

- I dropped the semicolon ; as a separator for arguments, as it is entirely superfluous and there is no need for the programmer to type it or the parser to be concerned with it; this means that the only separating characters are the whitespace characters, exactly as in pure S-expressions

- The primary bracketing characters are square brackets (`[]`) instead of parentheses; the reason for that design choice is that these are easier to type than parentheses or curly brackets (as they do not require holding the shift key), which matters considering the ubiquity of these characters in the source code

---

[3]`http://ceaude.twoticketsplease.de/js-lisps.html`
[4]`http://c2.com/cgi/wiki?LostInaSeaofParentheses`
[5]`http://www-formal.stanford.edu/jmc/recursive/node3.html`

- Expression's operator name is written before the opening bracket that precedes the list of arguments, as in `operator[argument-1 argument-2 ... argument-n]`

- I decided not to include any other syntax in the first prototype, as the one described so far is entirely sufficient to represent any Lisp-like expressions – it maps directly to S-expressions[6]

This gives a notation that is somewhat in between S-expressions and M-expressions. This was the basic syntax of the first prototype of the language. It can be defined[7], using pure, left-recursion-free BNF notation with the addition of a regular expression (between / delimiters) in the definition of `<word>`, as follows:

```
<expression>      ::= <word> | <call>
<call>            ::= <operator> <argument−list>
<operator>        ::= <word> <argument−lists>
<argument−list>   ::= "[" <arguments> "]"
<word>            ::= /[^\s\[\]]+/
<argument−lists>  ::= <argument−list> <argument−lists>
                      | ""
<arguments>       ::= <expression> <arguments> | ""
```

The regular expression can be read as "any character which is not whitespace, [or]". This means that aside from whitespace, which acts as expression separator there are only two special characters – the square brackets – that the parser have to worry about. For this reason it is very trivial to implement.

The above – somewhat verbose – definition is obviously somewhat similar to a Lisp BNF description[8].

An example of a valid expression in light of this definition would be:

```
do [
    bind [a 3]
    bind [b 5]
    bind [is−a−greater if [>[a b] true false]]
    is−a−greater
]
```

Where[9]:

---

[6]Any additions can be considered syntax sugar. Such syntax extensions were introduced in later prototypes and designs and some of them are included in the final prototype included with this thesis; see [|||]

[7]This definition is included here only for the sake of formality. I believe that for such a simple grammar BNF seems to introduce more noise and is unnecessarily more complex than a textual description in terms of regular expressions or simply verbatim parser source code. For these reasons any extensions to this basic grammar will later on be described in these ways.

[8]`http://www.cs.cmu.edu/Groups//AI/util/lang/lisp/doc/notes/lisp_bnf.txt`, `http://cui.unige.ch/db-research/Enseignement/analyseinfo/LISP/BNFlisp.html`

[9]Note: I will introduce brief definitions of language constructs as they appear in the presented listings. For a comprehensive list of primitives and functions see Section 3.4 of this chapter.

- `do` is a language primitive that serves the role of a single block of code, much like blocks delimited by `{` and `}` in C-like languages.

- `bind` is a basic construct for defining variables, like `var` or `define` in other languages.

- `if` serves as a basic conditional evaluation construct. Its semantics are like those of the analogous construct in Lisp.

Advantages of this M-expression-based notation over S-expressions are:

- Easier to parse by a human. Operators are clearer distinguished from operands. This is arguably because this notation is more familiar, bearing a similarity to the general mathematical notation (as in `f(x)`) and the most popular programming language syntax – the C-like syntax[10]

- If an expression has another expression as its operator, it is written as `op[args-1][args-2]`, which reduces the amount of nesting and thus the amount of bracketing characters appearing next to each other in the source code. Compare the equivalent S-expression: `((op args-1) args-2)`; and with multiple levels: `op[args-1][args-2][args-3][args-4]` vs `((((op args-1) args-2) args-3) args-4)`

An interesting property of this syntax, that, depending on the context could be classified as advantage, disadvantage or neither is that the sequence of characters `[[` is not legal, whereas in Lisp the analogous sequence `((` is.

Alas, this simple notation doesn't do away with a lot of other problems inherent in any minimal syntax, because such syntaxes have the property of being very homogenous. In the next subsections and later throughout this thesis I gradually introduce extensions, which make the syntax a little bit more diverse. Keep in mind that every special character that is introduced, is taken away from the set of possible `<word>`-characters, which implies that the regular expression for `<word>` is changed accordingly.

3.3.2 Comments, whitespace and the syntax tree

The parser was further extended with support for comment syntax similar to the ones found in Ada, Haskell or Lua:

```
-- a comment that extends until the end of the line
-- an expression that computes square root of 81:
sqrt[81]
```

---

[10]See `http://www.tiobe.com/tiobe_index`; 11 out of the top 20 languages as of June 2016 have C-based syntax (by this classification: `https://en.wikipedia.org/wiki/List_of_C-family_programming_languages`). If we extend the syntax family to Algol-like, its virtually 20 out of 20 – `http://www.martinrinehart.com/pages/genealogy-programming-languages.html`. There are no languages with Lisp-based syntax among the most popular ones.

```
−−[
    this is a multiline comment

    −−[
        multiline comments can be nested

        as long as [ and ] are balanced ,
        anything can be nested within
        multiline comments

        for example :
        −−[this is a comment that includes
        a piece of code *[7 7] ,
        which would evaluate to 49]
    ]
]
```

In principle multiline comments could be implemented simply with the syntax analyzer checking the operator of the expression being parsed, and if it is -, treating such expression as a comment. The fact that this expression was already parsed and transformed into a structural tree-like form could be taken advantage of while generating documentation from comments. For example we could define a following Domain-Specific Language[11] for documentation:

```
−−[
    −− the below is a documentation comment
    −− followed by the documented piece of code :
    −−[[
        Calculates the circumference of the Circle .

        override !
        deprecated !

        this [ circle ]

        −− The circumference of the circle :
        return [number]
    −−]]

    define [ calculate−circumference procedure [
        mul[2 math.pi this.radius]
    ]]
]
```

_____

Nevertheless the implementation in the prototype treats the comments as a stream of characters, taking into account nesting and balancing of brackets, but doesn't keep them as a tree-like structure.

Whitespace characters and comments have no semantic significance, unless serving as separators could be considered one. After building the syntax tree, bracketing characters also serve no purpose and can be safely be discarded, without influencing the interpretation of the program.

Despite this, all of these are included in the syntax tree generated by the parser. Storing these characters in the syntax tree means that the entirety of the textual representation, in structural form, is accessible by any other representation we might devise. This allows for implementation of variety of interesting "smart" language and editor features.

A thing to note at this point is that such syntax tree can't be described as "abstract"[12], as it includes all of the "concrete" syntax, with its runtime-insignificant elements. The syntax tree that is built for the Dual language is also later extended with references to other representations of code. For these reasons, I will later on use the acronym Enhanced Syntax Tree to refer to the representation used internally by the Dual language interpreter.

This representation greatly simplifies the implementation of and integrates with the language the following features:

- Automatic indentation

- Documentation comments. Comments can easily be associated with corresponding code blocks (syntax tree nodes), which can be useful for automatically generating documentation in any format

- Any expression can be unparsed to its original form straight from syntax tree, which can be used for debugging

- This also means that any expression can be stringified on-the-fly and this string can be used as a value in the program. This feature allowed me to completely omit definition of strings at the parser level, although this is not a very efficient solution. Nevertheless keeping strings in such structural form – as syntax trees – in combination with pattern matching enables language-native structural manipulation of strings[13][14]. For example we could write:

---

[12]According to these definitions: `https://en.wikipedia.org/wiki/Abstract_syntax_tree`, `http://c2.com/cgi/wiki?AbstractSyntaxTree`

[13]See: `https://reference.wolfram.com/language/tutorial/WorkingWithStringPatterns.html` and `https://en.wikipedia.org/wiki/Pattern_matching#Pattern_matching_and_strings` for similar concepts.

[14]I chose the structural representation as the only representation, because the performance penalty is acceptable in the prototype implementation. An obvious and very simple optimization would be to keep the raw form of the string as a value in the corresponding syntax tree node. Having these two forms alongside each other would enable the programmer to use the familiar string manipulation methods as well as structural manipulation.

```
bind  [ str  ' [A quick  brown  fox  jumps  over
               the  lazy  dog ] ]

bind  [ words  [_  _  third−word  { rest } ]  str ]

bind  [ characters  [_  _  third−letter  { rest } ]
        third−word ]

−−  logs  "o"  to  the  console :
log  [ third−letter ]
```

Where `words` deconstructs a string into single words and binds these words to identifiers provided as its arguments and `characters` performs an analogous operation on the single character-level. The notation `{rest}` matches zero or more arguments (see Section 3.3.6 for details). `log` outputs the values of its arguments to the JavaScript console.

Such representation was implemented in order to fulfill the design goal of direct and complete mapping of the textual representation into any other representation.

3.3.3 Numbers

Numbers in the language are represented as JavaScript numbers. This means that there's only one number type – 64-bit floating point[15]. They are implemented as follows:

- When a word is tokenized by the parser, it is converted to a JavaScript number with a Number type constructor, which returns either the corresponding value (if the word is parsable to a number) or the value `NaN`. In the former case, the numerical value is stored in the appropriate syntax tree node, as its `value` property.

- Upon evaluation, a syntax tree node is checked for the `value` property. If it has one it is given as the result of the evaluation.

- The fact that a number is stored as a syntax tree node, which contains the its string representation and its raw value, both obtained from the source code during parsing means that conversion from a number literal to string is zero-cost, which could be useful for optimization.

This shows a possible way of optimizing the representation of strings, which I intend to introduce in a future version of the language.

---

[15]Defined by the IEEE 754 standard: `http://www.iso.org/iso/iso_catalogue/catalogue_tc/catalogue_detail.htm?csnumber=57469`, `http://www.2ality.com/2012/04/number-encoding.html`

3.3.4 Zero and single argument expressions

In order to reduce the amount of *closing* brackets appearing next to each other in program's text, two additional simple notations were introduced. The first is addition of the pipe special character (|). This character is used for single-argument expressions, as in:

```
—— compute factorial of 32:
factorial |32 —— equivalent to factorial [32]

—— find 9th Fibonacci number:
fibonacci |9 —— <=> fibonacci [9]

—— compute sine of pi
sin | pi —— <=> sin [ pi ]

—— compute cosine of the number that is the result of
—— multiplication of pi and 5!:
cos |*[ pi factorial |5] —— <=> cos [*[ pi factorial [5]]]

—— convert 33.2 to an integer (truncate .2):
to−int |33.2 —— <=> to−int [33.2]

—— construct a list with one item,
—— which is a string "hello"
list | '| hello —— <=> list [ '[ hello ]]
```

The above example shows that if a function is invoked with one argument, we can omit the closing brace and replace the opening brace with |. The parser produces equivalent syntax tree.

Another special character (!) was introduced for analogous use for zero-argument expressions (procedures):

```
—— invoke a procedure that changes some
—— state variables in its outer scope:
set−initial−state ! —— <=> set−initial−state []

—— sum two random numbers:
—— <=> +[random []  random []]:
+[random !  random !]

—— bind a value returned by
—— an immediately invoked procedure to
—— an identifier
—— <=> bind [forty−two procedure [42][]]
bind [forty−two procedure [42]!]
forty−two —— evaluates to 42
```

In combination with macros

A unique macro system, described in Chapter 6[16] in combination with these two
(| and !) special characters help reduce the amount of bracketing characters even
further.

For example, if we define a `match*` and `of*` macros as described, the following
expression:

```
bind [x 99]

—— will log "x is greater than one":
match* [x]
| of* [<|0] [log|'[x is negative]]
| of*   [0] [log|'[x is zero]]
| of*   [1] [log|'[x is one]]
| log|'[x is greater than one]
```

which is somewhat similar syntactically to ML-style[17] languages, could be trans-
lated into the following:

```
bind [x 99]

—— will log "x is greater than one":
apply [
    of [<|0 log|'[x is negative]
        of [0 log|'[x is zero]
            of [1 log|'[x is one]
                log|'[x is greater than one]
            ]
        ]
    ]
    x
]
```

where `apply` would be defined analogously to Lisp's `apply`. `of` would be defined
as a function primitive with arity 2..*, which treats its penultimate argument as
the function's body and all the preceding arguments as patterns for the function's
arguments. The last argument is used when such a function is called and the values
supplied as arguments don't match the patterns. If the argument is a function, it
will be called with the same values as arguments and if it's a value it will be
returned.

I used such a solution for pattern matching in the early prototypes, but replaced
it with a native `match` construct (described in Section 3.4) for performance reasons.

---

[16]This macro system is not included in the final version of the prototype, although a proof-of-
concept of it that I implemented in earlier prototypes is the basis for this description.

[17]https://en.wikipedia.org/wiki/Standard_ML#Algebraic_datatypes_and_pattern_
matching

Nevertheless this shows that a few simple, but general syntax rules and a powerful macro system, can be a very flexible tool for extending syntax.

The pattern matching mechanism is explained in the next subsection.

3.3.5 Pattern matching

A simple, yet powerful pattern-matching facility was added to the language.

Pattern matching works with bindings, functions (although the primary function-producing expression in the prototype doesn't use it by default), `match` primitive and macros (not available in the prototype).

The pattern matching works in a way similar to most other languages that support this feature (e.g. ML family). The general rules are[18]:

- A literal (strings or numbers are supported) value matches itself:

```
—— computes factorial of a number
bind [factorial
    of [0 1
    of [n *[n factorial[−[n 1]]]]]]
]

—— logs '120':
log [factorial|5]
```

- An identifier (word) matches any value, which is then bound to the identifier:

```
bind [simple−print of [x log|x]]

—— logs '3':
simple−print[3]
```

- A wildcard pattern (_) matches any value, but doesn't bind:

```
—— returns its third argument,
—— discards the rest:
bind [get−third of [_ _ x x]]

—— logs '3':
log [get−third[1 2 3]]
```

  As such it can be useful for discarding some values, depending on other values or extracting some values from a structure (see next point).

- The following expression-patterns are supported:

---

[18]For brevity I assume here that 'of' is a primitive that works like described in 3.3.4, where the alternative argument is optional. This is how it was implemented in an early prototype of the language. If no viable alternative was present, an error was thrown.

- **list** or **$** is used to destructure lists:

```
bind  [$[_ _ third-element]  $[0  1  2]]

-- logs '3'
log  [third-element]

-- it works  for  arbitrarily  nested
-- lists  as  well
bind  [
    $[  _ $[  _ pick  _  _]  _]
    $['|a $['|b  '|c  '|d  '|e]  '|f]
]

-- logs 'c':
log  [pick]
```

- Comparison operators (= < <= >= <>) match if a value passes the comparison; it can be viewed as a shorthand notation for simple guards[19]:

```
-- returns  the  sign  of  a  number
-- note:  '-#'  is  the  unary  '-' operator:
bind  [sign of [=|0       0
          of  [<|0  -#|1
          of  [>|0       1]]]
]

-- logs '-1':
log  [sign|-77]
```

-

- Other pattern-expressions are not supported and using them will result in a mismatch.

The above examples show pattern matching used for destructuring values and binding their components to identifiers and for function definitions. There's also a **match** primitive, which can serve the role of a **switch** statement from C-like languages. Although pattern matching makes it much more powerful than that, as any values supported by the pattern matching system can be matched, including lists, which allow us to switch on multiple values and in any combinations.

The **match** primitive's first argument is a value to match and all subsequent arguments are two-element lists, where the firs element is the pattern to match and the second is the expression to evaluate in case of a match. The primitive tries the matches in order and only evaluates the expression, related to the successful match, which is the first one that matches. The subsequent matches are not evaluated.

---

[19]https://en.wikibooks.org/wiki/F_Sharp_Programming/Pattern_Matching_Basics#Using_Guards_within_Patterns

```
bind [state '|game-on]

-- will execute the 'play' procedure:
match [state
    $['|game-on play!]
    $['|game-paused display-pause-menu!]
    $['|game-screenshot capture-screenshot!]
]

-- ...

-- note: . is the access operator
-- .[a b c] is equivalent to a.b.c in other languages
bind [$[x y] .[player postion]]

-- we can easily replace complex conditions:
match [$[x x y y]
    $[
        $[>|0 <|screen-width >|0 <|screen-height]
        log|'[player visible]
    ]
    $[_ log|'[player not visible]]
]
```

•

With an arsenal of these few simple pattern matching tools we can use a lot of useful features, which further add expressivity to the language. We can also imagine many possible extensions and generalizations, as briefly discussed in Chapter 6.

• Destructuring assignments or, more precisely, destructuring definitions.[20]. An example of such definition would be:

```
bind [$[a b $[c d]] $[1 2 $[3 4]]]
bind [
    $[ _    x    y  {  rest  }]
    $['|a '|b '|c '|d '|e '|f]
]

-- logs '1 2 3 4':
log [a b c d]

-- logs 'b c ["d", "e", "f"]':
log [x y rest]
```

---

[20]Destructuring could easily be extended to mutation as well, although I have found it sufficient to be usable only in definitions, while implementing the prototype.

3.3.6 Rest parameters and spread operator

Another syntax extension that I introduced involved two additional special bracketing characters: { and }, which serve several purposes:

- Rest parameters mechanism known from Lisp[21], recently also adopted in JavaScript (as of the ECMAScript2015 standard[22]). That is, for example:

```
bind [ variadic−function of [a b {args}
    log [a b args]
]]

−− logs '1 2 [3, 4, 5, 6]':
variadic−function [1 2 3 4 5 6]
```

This enables the user to easily define variadic functions, which can be called with a variable number of arguments. This works in any place, where pattern matching works:

```
bind [$[a b {rest}] $['|a '|b '|c '|d '|e]]

−− logs '["c", "d", "e"]'
log [rest]
```

thus enabling non-exact matching.

- Spread operator (also inspired by the analogous feature from ECMAScript2015):

```
bind [f of [a b c d e f log [a b c d e f]]]
bind [args $[8 7 6]]

−− logs '9 8 7 6 5 4':
f [9 {args} {$[5 4]}]
```

This provides a much nicer and more powerful alternative to `apply`, Lisp's fundamental function, which applies a function to a list of arguments. It's a way to flatten any list onto a list of arguments. This works for multiple values and lists as well:

```
−− alternative way to achieve the same
−− result as in the previous listing
−− logs '9 8 7 6 5 4':
f [{9 args $[5 4]}]
```

- String interpolation notation:

---

[21]https://www.gnu.org/software/emacs/manual/html_node/elisp/Argument-List.html
[22]https://developer.mozilla.org/pl/docs/Web/JavaScript/Reference/Functions/rest_parameters

```
bind [ name ' | Bill ]

— logs 'Hello , Bill .'
log [ '[ Hello , { name } . ] ]
```

As we can see this gives us a very convenient notation for string interpolation, similar to e.g. template literals in JavaScript[23]. In order to escape curly braces, they should be doubled:

```
— logs 'Hello , { name } . '
log [ '[ Hello , {{ name }} . ] ]
```

I also added a special type of string – an HTML string, where interpolation notation is the other way around – double braces cause substitution, single braces do nothing:

```
bind [ name ' | Bill ]
— logs '<h1>Hello , Bill.</h1>'
log [ html '[<h1>Hello , {{name}}.</h1>]]

— logs '<h1>Hello , {name}.</h1>'
log [ html '[<h1>Hello , {name}.</h1>]]
```

This is to enable embedding CSS and JavaScript code inside those strings, without having to constantly escape brace characters.

- Unquote notation for macros[24] – see Chapter 6.

on duality of binding and evaluation expand in chapter 6 ?? optional parameters
Strings can be represented structurally, as syntax trees. This, in combination with pattern matching allows for
[?] Between S and M expressions
introduce it, but state that BNF ain't good and that it's not the best way of looking at such a simple language, only complicates reasoning

3.4 Basic primitives and functions

rest parameters and spread
log
list/$ Below is a description of the primitives and functions supported by the Dual language. Each item is structured as follows:

---

[23]https://developer.mozilla.org/en-US/docs/Web/JavaScript/Reference/Template_literals

[24]Analogous to unquote or , in Lisp: https://docs.racket-lang.org/reference/reader.html#%28part._parse-quote%29

- `<name> [<arguments>]`

  ⟨description⟩

  Where `<name>` is the name of the function/primitive and `<arguments>` are either the names that describe the arguments of the function/primitive or its arity. That is, the number of arguments that the function/primitive is defined for. This can be a fixed value (e.g 1), a fixed range of values (e.g. 0..3) or a range of values without an upper bound (e.g. 0..*, which means 0 or more).

  ⟨description⟩ is a brief description of the function/primitive.

3.4.1 Language primitives

The Dual language supports the following primitives:

- `do [0..*]`

  Evaluates its arguments in order and returns the value of the last argument.

- `bind [name value]`

  Evaluates its second argument and binds this value to the name of the first argument. This name is bound within the current scope. This is a basic construct for defining variables, like `var` or `define` in other languages. Significant semantics here are that new scopes are introduced by function bodies, macro bodies and match expression bodies. The primitive also supports pattern matching to deconstruct the value and bind its components to possibly several variables. In that regard it works a lot like JavaScript's destructuring assignment[25] or similar features in other languages, such as Perl or Python. This primitive can be used only for binding names that don't exist in the scope at the point of its invocation. There are other constructs for mutating and modifying existing variables. There is no hoisting[26], as definitions are processed in order in which they appear in code.

- `if [condition consequent alternative]`

  This primitive serves as a basic conditional evaluation construct. Its semantics are like those of the analogous construct in Lisp. It accepts 3 arguments: first the `condition` expression, then the `consequent`, that is, the expression to be evaluated if the value of the condition is *not false* (note that this is a strict rule; any other value than `false` is interpreted as `true`; every conditional construct in the language follows this rule). The third argument, the `alternative` is the expression that is evaluated otherwise.

---

[25]https://developer.mozilla.org/pl/docs/Web/JavaScript/Reference/Operators/Destructuring_assignment

[26]https://developer.mozilla.org/en-US/docs/Web/JavaScript/Reference/Statements/var#var_hoisting

- `while [condition body]`

  A basic loop construct. If `condition` is equivalent to *not false*, evaluates `body`. Repeats these steps until `condition` evaluates to `false`. Returns the value of the last evaluation of `body` or `false` if the body was not evaluated.

- `mutate* [name value]`

  If a variable identified by `name` is defined within the current scope or any outer scope, changes (mutates) its value, so it now refers to the result of evaluating the `value` argument. The scopes are searched from the innermost to the outermost, in order. If the `name` argument doesn't identify any variable, an error is thrown. Returns the scope (environment), in which the primitive was evaluated. [[first-class environments, Bla paper?]]

- assign

- .

- :

- @

- dict*

- async*

Basic functions and values:
[[|]] Mapping to a JavaScript equivalent

- `true` and `false` evaluate to their respective boolean values. `_` is an alias for `true` when used outside of pattern-matching. This enables a convenient compatibility between `match` and `cond`: if we're matching a single value and want to have a default case, then `_` is used to match any value. Similarly, if `_` is given as a condition in the last alternative of `cond`, it will evaluate to `true` and work as the default case.

- `undefined` evaluates to JavaScript's undefined[[link]].

- `typeof` wraps JavaScript's `typeof` operator.

- `or` and `and` are the basic logical operators – analogous to `||` and `&&` in JavaScript.

- `any` and `all` are like the above, but accept variable number of arguments. These return either `true` or `false`.

- `not` is the negation operator (`!`)

see text files ideas

language's syntax/grammar language's grammar in BNF-notation, without left-recursion, a bit verbose: <expression> ::= <word> | <call> <call> ::= <operator> <argument-list> <operator> ::= <word> <argument-lists> <argument-list> ::= "[" <arguments> "]" <word> ::= /$^[$]+/ <argument-lists> ::= <argument-list> <argument-lists> | "" <arguments> ::= <expression> <arguments> | ""

less verbose (not sure if correct): <expression> ::= <word> <expression-lists> <word> ::= /$^[$]+/ <expression-lists> ::= "[" <expressions> "]" <expression-lists> | "" <expressions> ::= <expression> <expressions> | ""

whitespace is mostly non-significant; it doesn't influence the semantics of a program, although it is stored in the syntax tree and can be accessed by special primitives, such as 'string'

language's semantics AST is a tree of nested expression objects there are two types of expressions: word an identifier/name usually refers to some value in the accessible scope could also be treated as literal string (possibly parsed to a number), depending on the operator that evaluates it call an application consists of an operator (which is an expression that is being applied) and arguments (which are fed to the operator) should produce a value

every language element is an expression and has a value

define aliases: : arity: 2 arguments: name, value description: creates a value accessible in the closest scope under the 'name' label; the value is the result of evaluating 'value' returns: the result of evaluating 'value'

sequence aliases: seq, do arity: * (0..infinity) description: evaluates its arguments in order return: the value of its last argument

string aliases: $arity : *description : returns its arguments' names and the whitespace between the$ wolrd!] would be more-or-less equivalent to Java string: "Hello, world!" notes: this kind of string is multiline and could work with embedded expressions, as in: $[Hello, \$[name]!]if 'name' would refer to another string of value e.g. "Alan" this would produce a strin$ $"Hello, Alan!"$

if aliases: conditional arity: 3 arguments: condition, then-expression, else-expression returns: if 'condition' evaluates to 'true', the value of 'then-expression', otherwise the value of 'else-expression' alternatively the condition could be checked against a non-zero value instead of 'true' note: I will most likely drop the concept of booleans

entirely and treat 0 as a special value, representing 'false', 'null', 'undefined', empty any non-zero value would then represent 'true'

while arity: 2 arguments: condition, loop-body description: a basic loop construct; if 'condition' is equivalent to 'true', evaluates 'loop-body'; repeats these steps until 'condition' evaluates to 'false' (0) returns: 'false' (0)

number aliases: # arity: 1 description: parses its argument's name as a number, as in: #[3] evaluates to the number 3 returns: a number parsed from its argument's name

boolean aliases: ? arity: 1 description: parses its argument's name as a boolean, as in: ?[true] evaluates to 'true' returns: 'true' or 'false', depending on its argument name note: likely will be dropped from the language

print $arity : *description : works like 'string', but also prints its value to the JavaScript console$

todo: greater-than aliases: >, gt arity: 2 arguments: a, b description: checks if 'a' is greater than 'b' returns: 'true' if 'a' greater than 'b', 'false' otherwise alternatively 'a' if 'a' greater than 'b' and non-zero, infinity if 'a' equal to zero, but greater than 'b' and zero otherwise

less-than aliases: <, lt description: analogous to greater-than, only checks if 'a' less than 'b'

...other operators and common functions

function aliases: fun, / arity: 1..* arguments: arg* (zero or more), function-body description: creates a function value all the arguments up to the last are the names of the function arguments (must be identifiers); the last argument is the 'function-body' returns: a function that accepts the defined number of arguments and evaluates them in the context of the 'function-body'; such a function creates its own local environment on top of the environment it is defined in, puts the argumens it was called with in this environment, under the defined labels and evaluates the 'function-body' in this environment; the return value is the value of the 'function-body'

// branch // switch // array // set

special elements (not implemeted): description: interpreter switch; precedes an interpreter command (which is a valid language identifier), which changes (possibly temporarily) the behaviour of the interpreter for example: if flag then-do-this else-do-this would be equivalent to: if[flag then-do-this else-do-this] here   executes a numerical command (3) that makes the interpreter treat next 3 expressions as arguments to the preceding expression, which would be applied to them this would be a simple way of getting rid of excess closing brackets ']' I have a few other ideas to utilize the interpreter switch, such as comments/documentation.

3.5   Basic functions

3.6   Memory model

language's "memory model" to call it a memory model is a stretch; every program is evaluated in an environment, which is a JavaScript object (basically a string

key-any value map); the keys in the environment object are variable names/identifiers; the values are the values associated with the corresponding identifiers; the environment that is accessible at all times is the root environment, where all globally-accessible values live it should be populated with basic arithmetic and logic operators, functions and constructs that are not special language primitives (such as if, while, string, etc.) all functions defined in the language have their local environment, build on top of the environment that contains the function definition (closures work) functions have access to values in their local environments and all containing environments the local environment can have identifiers defined that override outer enivronments' identifiers (but they don't overwrite them) this mechanism is built on top of JavaScript's prototype-based inheritance

Since it is a thin wrapper over JavaScript it shares its memory model. Event loop Single-threadedness

3.7 Syntax extensions

rest parameters spread operator built-in template strings, quotation mechanism html strings

3.8 Pattern matching

Chapter 4

Development environment

4.1 Overview

A folder is considered a project, similarly to modern code editors, such as Brackets or Visual Studio Code.

The current version of the development environment is intended to be used offline, on user's machine. Nevertheless it is designed so that it could be easily transformed into an online system.

I decided to implement the system with minimal dependencies, so it can be easily installed and so I can achieve a greater level of integration by having more control over every part.

The only required dependency for the basic functionality of the prototype to work (which is the editor) is a web browser and the CodeMirror library. An additional dependency is the Node.js environment.

The language's development environment is implemented as a web application. It consists of three parts:

- The server part, implemented in JavaScript on top of Node.js. This part's functions is mainly to enable access to user's file system, so any local folder can be opened as a project – modern web browsers restrict access to the local file system, because of security reasons. The server part also handles persisting changes to files and configuration.

- The project manager part, which communicates directly with the server part. The connection is maintained over a WebSocket[1]. This part provides access to user's file system via a custom folder selection interface. Basic configuration of server communication, such as changing the address and ports is also possible. Once a project is selected, the user may open it in the editor part.

- The editor part, which is the main component and can function as a stand-alone application. It can communicate with the server indirectly, through the `localStorage` mechanism[2].

---

[1] https://developer.mozilla.org/pl/docs/WebSockets
[2] https://developer.mozilla.org/en-US/docs/Web/API/Window/localStorage

The project manager and the editor, which can be considered the front-end parts of the system are designed to be a Single-Page Application[3]. The project manager exchanges JSON messages with the server through a WebSocket. This is used for updating the view with dynamic data. In order to facilitate the manipulation of the HTML structure of the page, which is the main application's view, I implemented a very simple web application framework, which binds the data from the server with the data on the client and the Document Object Model[4].

Figure 4.1: The editor

Figure 4.1 shows an overview of the editor prototype's window. The basic layout is modeled after the aforementioned code editors. At the top of the window is the menu bar, below a global search input (not implemented in the prototype). The left panel contains basic controls for selecting examples, invoking the parser and interpreter, toggling application view and adjusting the scale of the visual representation.

The following options are implemented in the prototype:

- Available from the menu bar:

    - File->Save, which saves the current content of the text editor to a file named `save.dual` in editor's root directory. This only works if the server-side part of the environment is running. Otherwise the source will be saved only to browser's internal storage.

    - In the Edit menu: Undo, Redo, Cut, Copy, Paste and Select All options are supported. Note that by default web browsers restrict the access

---

[3]https://en.wikipedia.org/wiki/Single-page_application
[4]http://eloquentjavascript.net/13_dom.html

to the user's clipboard, so for Copy and Paste the standard key short-
cuts should be used (Ctrl-C, Ctrl-V). All other conventional keyboard
shortcuts are also supported, thanks to the CodeMirror library.

- Available from the left panel:

    - The options in the Examples submenu cause a corresponding source file
      to be loaded into the editor. This is for demonstration for the purposes
      of this thesis.

    - The Options submenu allows the user to invoke the parser and the
      interpreter separately or in combination as well as toggling between
      the "page" (also known as "application") and visual editor views. The
      application view contains an embedded web page (iframe), which can
      be manipulated by a Dual application. This is used to display the game
      view in the Pac-Man clone example.

    - The Visual scale submenu changes the size of the blocks in the visual ed-
      itor. This demonstrates how manipulating one CSS property influences
      the rendering of the visual representation.

Some options have descriptive captions available that appear when the mouse
cursor hovers over them.

4.2 Text editor

The text editor is built on top of the CodeMirror framework[5]. It was integrated
with the editor in the following way:

- A custom syntax highlighting mode for Dual was defined.

- If a position of the text cursor in or the contents of the source change, a
  fragment of text corresponding to the appropriate EST node is highlighted.
  Also the corresponding subtree in the visual editor is highlighted. This works
  also in the other direction – when a node in the visual editor is selected, it is
  highlighted along with the corresponding text fragment. This demonstrates
  the core functionality of the system: it is "aware" at all times of currently
  focused meaningful part of the code, corresponding to an EST node. This is
  reflected in every representation that is associated with the EST.

A naive implementation of
Because every node in the EST is linked in both directions with a corresponding
abstract element in a representation, any change to the element can be reflected in
the node and, through the EST, in all other associated representations. This makes
the system accurate and fast, as every change happens in an isolated context, which
doesn't have to be reestablished every time a modification is made.
We can distinguish three representations used by the system:

---

[5] https://codemirror.net/

1. The EST, which is the master representation of the program.

2. The fragments of text corresponding to EST nodes in the text representation are tracked by CodeMirror's TextMarker objects. These facilitate tracking and propagating any changes to and from this representation, as well as highlighting.

3. The visual representation, which is implemented in terms of pure HTML tables fully styled with CSS. This allows for easy and complete customization of the representation.

Figure 4.2: Visual editor's context menu

In case of the visual representation this is implemented in a rather straightforward way: every EST node has a corresponding set of DOM nodes. Thanks to this, we can track any actions performed on the DOM through the standard browser-implemented interface. This is solved in the prototype by attaching `click` event handlers to relevant nodes. Such an event triggers the following:

- A corresponding EST node is "focused" by the system.

- A context menu appears similar to that depicted in 4.2. This menu has basic options for editing the visual nodes: Replace, Add and Remove. These perform their corresponding action on the currently focused node and propagate it to all representations. The Remove option simply removes the selected node and its subtree from the DOM, the EST, as well as the associated text fragment. Add and Replace make use of the small text-editor area next to the context menu. It contains a list of possible names of nodes to be inserted in case the user wants to a node. Selecting any of the names causes a template for the new node (in the form of an editable code snippet) to be inserted into the text-editor area. Such a template can be quickly adjusted by the user before inserting. The user may also type in raw code into the text box, without selecting any templates. After entering the code and selecting the appropriate option, the text is parsed, transformed into TextMarker, EST and DOM representations. Then all the versions of the fragment are inserted in appropriate places.

The list of possible nodes displayed along with the context menu is implemented in terms of a simple autocomplete functionality on top of CodeMirror. Every item

in the autocomplete list is associated with a fragment of code, which is basically a signature of the corresponding function. User-defined functions could be easily automatically added to this list by extracting their signatures from definitions. Autocompletion should also be made context-sensitive, similarly to modern code editors.

The templates could also be selected by the user from a visual library of puzzle pieces, like the one in Scratch (Fig. 4.3).

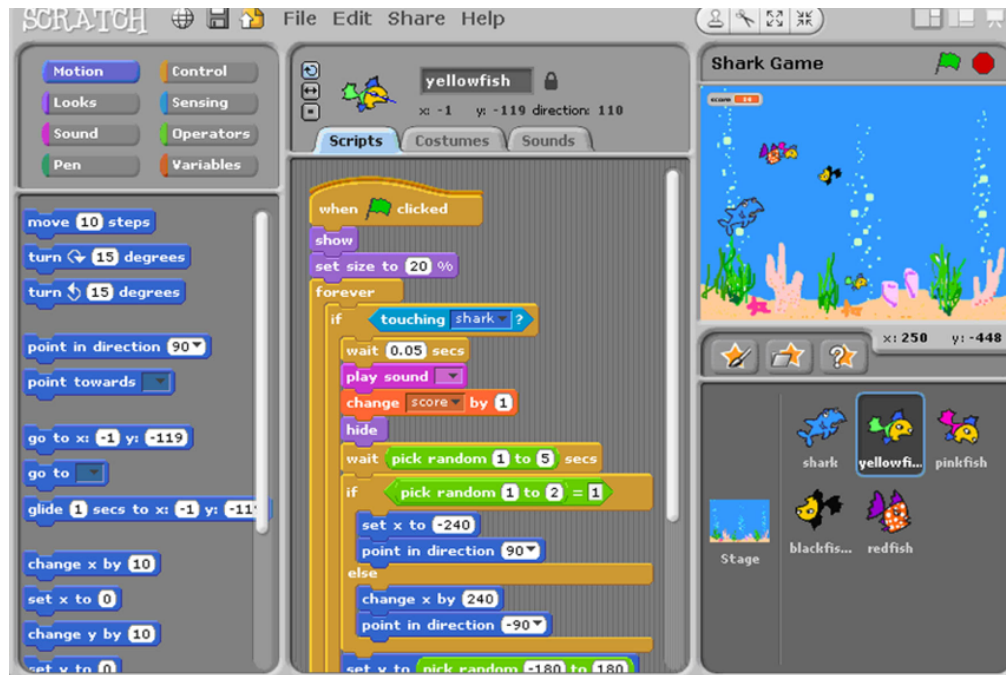

Figure 4.3: MIT Scratch programming language editor[6]

The templates prepared for the prototype use

Saving own templates

Possible improvements and enhancments to the visual editor: Support for more ways of manipulating the DOM representation, such as drag and drop.

A good design is not made overnight.

Smalltalk was perfected over 10 years.

Figure 4.6:

The goal is to build an online IDE, similar to Codeanywhere[7] or Cloud9[8], works offline as well.

Describe how the representations are *dynamically* mapped into each other.

angular data binding

simple syntax can be easily mapped into a visual, tree-like representation: basically we visualise the EST, with additional visual cues, widgets, etc. for language primitives, different datatypes, and other distinguishable elements

compare to unreal engine: see chapter 77

the interface is somewhat cumbersome, but allows for assembling any code that can be assembled with text rapid editing: replacing any subtree

4.4   Performance

Inefficient – unnecessary amount of DOM nodes is kept

It could be optimized similarly to CodeMirror or other web-based text editors or applications. That is, only a visible portion (plus a margin, which allows for fast scrolling) of the code is rendered as DOM nodes at any time. The scrollbar is virtual and controlled by the editor rather than the browser.

Text editors like CodeMirror use similar amount of DOM nodes [[|]], but thanks to these optimizations are able to handle megabyte-sized[9] text files and are used in many real-world applications[10], which includes being a built-in editor in developer tools in major web browsers.

Another source of inefficiency is that parsing is done twice – once by Dual's parser and once by CodeMirror's system, which are incompatibile. A solution to

---

[7]https://codeanywhere.com/

[8]https://c9.io/

[9]http://codemirror.net/doc/internals.html#approach

[10]http://codemirror.net/doc/realworld.html

that would be to implement a custom text editor or extend/modify CodeMirror to work with Dual's parser.

Chapter 5

Case study

Dynamic languages with a garbage collector have the advantage of letting the programmer use the exploratory style of programming, where he doesn't have to worry about memory management or other low level considerations. |||| Doesn't have to design a complex type hierarchy or any similar scaffolding. He can just jump in and start implementing an idea. This is excellent for prototyping.

But when it comes to performance and robustness this approach shows its downsides very quickly. The safety of static types combined with a good development environment catches a lot of bugs and inconsistencies before runtime. Garbage collector mechanisms vary in implementation, each showing a different performance characteristic. In this chapter I will describe the implementation of a clone of Pac-Man in Dual and performance issues that I've encountered. These are very much related to the JavaScript environment, notably the event loop and the garbage collector, which has different implementations across browsers. The latter did shows a significant difference when comparing different web browsers.

Implementation of a non-trivial application allows to test the language design and quickly establish which features are the most useful in practice. I found that I could do away with a lot of the more complex ones

5.1   The game

It is actually a port of my earlier clone of the game, which was written in Links[1], a functional language.

5.1.1   Main loop

A typical game loop in a modern JavaScript game[2] relies on the `requestAnimationFrame` method[3]. This method takes a single argument, which is a function callback. This

---

[1]`http://groups.inf.ed.ac.uk/links/`
[2]`https://developer.mozilla.org/en-US/docs/Games/Anatomy`
[3]`https://developer.mozilla.org/en-US/docs/Web/API/Window/`
`requestAnimationFrame`

Figure 5.1: A screenshot from the game

function is invoked by the browser before it repaints the contents of the window. Thus, it allows the game rendering to be synchronized with the browser.

The callback invoked by `requestAnimationFrame` receives a timestamp, specifying the time of the repaint event. Ideally and under the most common circumstances this happens 60 times a second.

I implemented the game loop in Dual as follows:

```
—— [1] the amount of milliseconds between
——       game state updates:
bind [tick−length 50]

—— the main loop function:
bind [main−loop
—— arguments:
——     game−state —— current game state
——     last−tick —— time of the last
——         game state update
——     fps−info —— an object used for debugging,
——         which contains information about
——          the frame rate
——       current−time —— the time of  the current
```

```
—        invocation of the loop
of [game−state last−tick fps−info current−time do [
    −− [2] schedule the next iteration of the loop
    −−       using requestAnimationFrame :
    async [
        .[ window requestAnimationFrame ]
        of [ next−time
            main−loop [
                game−state
                last−tick
                fps−info
                next−time
            ]
        ]
    ]

    −− the timestamp of the tick after the last tick
    bind [ next−tick +[last−tick tick−length ]]

    −− counts how many state updates should be
    −−       performed in this iteration :
    bind [ tick−count 0]

    −− if the current time is past the timestamp of
    −−       the next tick , the above counter
    −−       should be incremented ;
    −− possibly more than by one , if the difference
    −−       is a multiply of tick−length
    if [>[current−time next−tick ] do [
        bind [ time−since−tick
            −[current−time last−tick ]]
        mutate [
            tick−count
            .[ math floor ][
                /[ time−since−tick tick−length ]
            ]
        ]
    ] false ]

    −− perform the calculated amount of
    −−       game state updates :
    bind [ i 0]
    while [<[i tick−count ] do [
        −− keep track of the time of the last tick :
        mutate [ last−tick +[last−tick tick−length ]]
```

```
        -- invoke the function that updates
        --       the game-state:
        mutate [
            game-state
            main-game-logic [game-state input-queue]
        ]
        mutate [i +[i 1]]
    ]]

    -- if there were game state updates,
    --       redraw game screen; else do nothing:
    if [>[tick-count 0]
        mutate [fps-info draw[
            game-state
            current-time
            .[window performance now]!
            fps-info
        ]]
        _
    ]
]]]
```

5.2 Performance

Disparity between Firefox and Chrome, reflecting differences in garbage collector implementations.

Issue: interpreter is blocking the event loop. There's a lot of intermediate objects created that have to be garbage collected.

General pattern:

Chrome more frequent garbage collections more regular more predictable

Details are a topic for another thesis

5.3 Possible improvements

Interruptable eval

Continuation-passing style State machine Anyway, explicit stack

Additional benefits: can pause and debug the application, step through can record the state and rewind

iterative-evaluate.js excerpt:

6.1   Comments

If multiline comments were implemented as expressions on parser-level then, in combination with | special character we could have one-word comments, which could be useful for describing arguments to facilitate reading of expressions. For example we could implement list comprehensions, where:

```
$<−[^[x  2]  x  range[0  10]]
$<−[$[x  y]  x  $[1  2  3]  y  $[3  1  4]  <>[x  y]]
```

would be equivalent to Python's[1]:

```
[x**2  for  x  in  range(10)]
[(x,  y)  for  x  in  [1,2,3]  for  y  in  [3,1,4]  if  x != y]
```

As we see this notation is acceptable (if not cleaner) for simple comprehensions, but starts being less readable for complex ones. This could be alleviated by introducing one-word comments:

```
$<−[^[x  2]  −−|for  x  −−|in  range[0  10]]
```

```
$<−[$[x  y]  −−|for  x  −−|in  $[1  2  3]
```

---

[1] https://docs.python.org/3/tutorial/datastructures.html#list-comprehensions

```
−−|for  y  −−|in  $[3  1  4]
−−|if  <>[x  y]]
```

which are easily inserted inline with code and have a benefit of clearly separating individual parts of an expression, because of being easily distinguished visually from the rest. This can simulate different syntactical constructs from other programming languages, like:

```
if  [>[a  b]  −−|then
    log['|greater]
−−|else  log['|lesser−or−equal]
]
```

Except that it is not validated by the parser. But we could imagine a separate or extend the existing syntax analyzer, so it could validate such "keyword" comments or even use them in some way. For example, we could add a static type checker to the language – in a similar manner that TypeScript or Flow[2] extends JavaScript. This would be completely transparent to the rest of the language, so any program that uses this feature would be valid without it and it could be turned on and off as needed.

To reduce the number of characters that have to be typed, we could decide to use a different comment "operator", such as %:

```
$<−[^[x  2]  %|for  x  %|in  range[0  10]]
```

```
$<−[$[x  y]  %|for  x  %|in  $[1  2  3]
             %|for  y  %|in  $[3  1  4]
             %|if  <>[x  y]]
```

```
if  [>[a  b]  %|then
    log['|greater]
%|else  log['|lesser−or−equal]
]
```

Or even, at the cost of complicating the parser, introduce a separate syntax for one-word comments:

```
−− '%:type' could  be  a  type  annotation
bind [a  3  %:integer]
bind [b  5  %:integer]

−− will  print  "lesser−or−equal"
if  [>[a  b]  %then
    log['|greater]
%else  log['|lesser−or−equal]
]
```

---

[2]`https://flowtype.org/`

In future versions of the language, comments will be stored separately from whitespace in the EST. This enables easy smart indentation – only a prefix of the relevant expression has to be looked at, no need to filter out comments. It also enables using comments structurally, as a metalanguage for annotations, documentation, etc.

6.2 Module system

6.3 Extensions to parameter pattern matching

proposed syntax optional parameters a b c default args ?[a 3] ?[b 4] ?[c 5]
elaborate on the duality/symmetry of binding/definition and evaluation
destructuring code for macros
matching arbitrary expressions/types

6.4 Structural string manipulation

```
words[_ _ _ fourth _ sixth] — supa fast, out of the box
characters[_ _ _ _ fifth]
```

6.5 First-class macros

implemented, but turned off/discarded in the final prototype need a rewrite (not within time scope of this thesis)
jit-expanded
work on zero-cost for simple cases works, but if nontrivial, in loops, nested, etc. then it's a complex problem
possibilities: compile-time macros
even more flexible system: read (parse) time macros // link to json in lisp
gensym, hygiene

6.6 A better evaluation model

better suited to the browser environment Explicit-stack execution model

6.7 C-like syntax

Throughout this thesis I introduced multiple ways in which the basic, Lisp-like syntax of Dual can be easily extended with simple enhancements, such as adding more general-purpose special characters, macros, single-word comments (as described in Section 6.1), etc.

Going further along this path, keeping in mind that a real-world language should appeal to its users we find ourselves introducing more and more elements of C-like syntax. This section describes more possible ways in which the simple syntax could be morphed to resemble the most popular languages.

direct mapping to the bare syntax

make syntax more heterogenous

.[a b c] a.b.c – THIS

minimalist approach to language design Paul Graham's Arc

renamed define to bind shorter, slightly specific meaning

mental gymnastics and thesaurus at hand

I prefer short but complete words

disadvantage is that changing the name of something fundamental makes it seem unfamiliar which is not necessary if the only thing that actually changed is the name/syntax and not the semantics

infix notation inside () `https://en.wikipedia.org/wiki/Shunting-yard_algorithm`

Ultimately all this could be implemented with a conventional complex parser for a C-like language that translates to bare Dual syntax. ||

Below I present a snapshot from one of designs I have been working on in order to achieve some goals described in this section:

```
fit map" {f; lst} {
    let {i; ret} [0, []];

    while ((i < lst.length)) {
        ret.push f(lst i);
        set i" ((i + 1))
    };
    ret
};
```

This would be equivalent to:

```
bind ['|map of ['|f '|lst do [
    bind ['[i ret] $[0 $[]]]

    while [<[i lst|length] do [
        ret[push][f[lst|@[i]]]
        mutate* ['|i +[i 1]]
    ]]
    ret
]]]
```

Using the notation presented in Chapter 3.

One may observe that:

- The syntax is much richer, somewhat C-like, but with critical differences, reflecting significantly different nature of the language. At a first glance, it

has a familiar look defined by blocks of code delimited by curly-braces, inside which statements (actually expressions) are separated by semicolons; there are different kinds of bracketing characters (`{}()[]`) with different meanings (described below)

- Names of the primitives are *full* English words, although as short as possible. `let` introduces a variable definition – similarly to `bind`. `fit <name> <args> <body>` is a shorthand for `let <name> (of <args> <body>)`, where `of` produces a function value. This translates to `bind [<name> of [<args> <body>]]`.

- `{}` delimit a string; inside a string words are separated by `;`. Strings are stored in raw as well as structural (syntax tree) form. They are a way of quoting code. This provides an explicit laziness mechanism. One-word strings are denoted with `"` at the end of the word, which resembles the mathematical double prime notation.

- `[]` delimit list literals; inside list literals, elements are separated by `,`. Lists are a basic data structure. They are actually objects, somewhat like in JavaScript. If a list contains at least one `:` character (not shown in the example), it will be validated as key-value container; if it doesn't, it will be treated as array with integer-based indices

- `()` are used in function invocations; `f(a, b, c)` translates to `f[a b c]`; `,` separates function arguments; `f x` is a shorthand notation for `f(x)`. This, in combination with currying primitives into appropriate macros allows for elimination of excessive brackets and separators. Invocations of primitives resemble use of keywords from other lanugages.

- But at the same time primitives are defined as regular functions – they are no longer treated exceptionally by the interpreter. When they are invoked, all of their arguments are first evaluated. This works, because now it is required that the programmer quote any words that shouldn't be evaluated, such as identifier names when using `let`. So primitives are just regular functions operating on code, thanks to the explicit laziness provided by strings.

- `(())` introduce an infix expression, which respects basic operator precedence: `((a + b * 2))` would translate to `+[a *[b 2]]`. This could be implemented with a separate parser based on the shunting-yard[3] or similar algorithm that is triggered by the `((` sequence. It would translate these infix expressions to prefix form and return them back to the original parser.

6.8 Modules

In principle import and module keywor

Podsumowanie jest, obok Wstępu, najważniejszym rozdziałem pracy. Należy tutaj jeszcze raz podsumować wykonane prace. Szczególny nacisk należy położyć na wkład własny autora i uzyskane oryginalne rezultaty. Należy odwołać się do celów pracy z rozdziału **??** – można je powtórzyć – i jasno wskazać, że zostały one zrealizowane (należy powołać się na wyniki z rozdziału **??**). Wyniki należy podsumować zwięźle i precyzyjnie, np. *uzyskano przyspieszenie algorytmu o X%...,* *skrócono czas o ...* itd. Należy wskazać perspektywy dalszych badań bądź zastosowanie uzyskanych rezultatów do rozwiązania problemów znanych z literatury.

Appendix A

Edycja i formatowanie pracy

Pracę należy przygotować korzystając z systemu składu LaTeX (czyt. *latech*). Bardzo dobre wprowadzenie do LaTeX stanowi "The Not So Short Introduction to LaTeX 2_ε" [?].

A.1 Kwestie techniczne

Aby móc składać dokumenty z użyciem LaTeX należy go oczywiście najpierw zainstalować. Dostępnych jest wiele dystrybucji LaTeX. Osobiście korzystam z TeX Live [?], dostępnego zarówno pod Windowsa jak i Linuksa. Dobrze jest również zaopatrzyć się w środowisko do LaTeX i BibTeX (o tym drugim więcej w sekcji A.3). Użytkownikom Linuksa polecam edytor Emacs [?] albo Kile [?] oraz program KBibTeX [?].

Wymagane jest przechowywanie pracy w repozytorium kodu źródłowego. Preferowanym systemem kontroli wersji jest git. Darmowe repozytoria gita można założyć w serwisie GitHub [?] albo, po kontakcie ze mną, na serwerze uczelni.

Do pracy dołączony jest plik `Makefile` służący do zbudowania pliku PDF ze źródłowych plików tex. Należy dbać o poprawne działanie tego pliku, np. po dodaniu nowego pliku źródłowego albo usunięciu istniejącego należy uaktualnić listę plików źródłowych w tym pliku.

A.2 Formatowanie

Należy zachować formatowanie zgodne z niniejszym szablonem. Wymagany jest druk dwustronny pracy. W związku z tym proszę zwrócić szczególną uwagę na położenie szerszego marginesu. Powinien się on oczywiście znajdować od strony bindowania.

Wszystkie ustawienia marginesów, stylu nagłówków, wykorzystanych pakietów etc. znajdują się w pliku `praca_dyplomowa.sty`.

Należy unikać wiszących spójników (zwanych też sierotami). W tym celu należy stosować po spójnikach twardą spację. W LaTeX uzyskuje się ten efekt poprzez umieszczenie pomiędzy spójnikiem a następującym po nim słowem znaku tyldy.

W celu ułatwienia tego procesu do szablonu dołączono plik `korekta.sh`. Jest to prosty skrypt basha – użytkownicy Windowsa muszą go dostosować do swojego systemu – który używa programu `sed` do wstawienia twardej spacji po spójnikach we wszystkich plikach z rozszerzeniem *.tex w bieżącym katalogu. Przed uruchomieniem skryptu należy dla bezpieczeństwa wykonać commit.

Przy składaniu pracy przydatny może okazać się tryb draft, który sprawi że zaznaczane będą miejsca w których tekst nie został prawidłowo złamany. Jeśli LaTeX nie potrafi prawidłowo złamać jakiegoś słowa można w preambule dokumentu użyć polecenia `hyphenation`.

A.3 Bibliografia

Wszystkie źródła informacji, rysunków, danych itd., które zostały wykorzystane przy tworzeniu pracy muszą zostać podane w bibliografii. Ponadto, wszystkie źródła podane w bibliografii muszą być cytowane w tekście. Za każdym razem, kiedy w pracy pojawia się treść na podstawie jakiegoś tekstu źródłowego czyjegoś autorstwa, oznaczamy takie miejsce cytowaniem [?, str. 9]. Należy wyraźnie zaznaczyć kiedy dokonywany jest dosłowny cytat z innej pracy. **Należy pamiętać, że korzystanie ze źródeł bez ich podania w bibliografii może być podstawą do oskarżenia o plagiat.**

Należy zwrócić szczególną uwagę na jakość cytowanych źródeł internetowych. Najlepszym rozwiązaniem jest ograniczenie się, na ile to możliwe, do oficjalnych stron projektów. Ponadto, odnośniki do źródeł elektronicznych muszą zawierać pełną ścieżkę do zasobu.

Bibliografię należy przygotować korzystając z mechanizmów dostarczanych przez LaTeX (patrz rozdział 4.2 w [?]). Zalecam korzystanie w tym celu z BibTeX. BibTeX sam wygeneruje bibliografię na podstawie przygotowanej prostej bazy danych i zagwarantuje że w spisie literatury pojawią się tylko te pozycje, które są faktycznie cytowane w pracy. Pozwoli to zaoszczędzić naprawdę sporo czasu.

Appendix B

Płyta CD
Do pracy należy dołączyć podpisaną płytę CD w papierowej kopercie. Poniżej należy zamieścić opis zawartości katalogów.

Zawartość katalogów na płycie:

dist – a runnable version of the prototype of the editor described in this thesis as well as all associated applications; also contains source files of all the applications

doc – electronic version of this thesis in PDF format and a presentation from diploma seminar.

ext – Node.js installer. Node.js is required to run the server-side of the application

src – only the source files of the applications developed in Dual

B.1   Running the application

It is assumed that you have a modern web browser compatibile with Firefox[1] 47 or Chrome[2] 51 – these were used in developing and testing the application. The source code is written using some ECMAScript2015 features, so it will not work on older browsers. In order to run the version distributed with this thesis, follow these steps:

1. If you want to run the server-side part of the application (it will work without it):

   (a) If you don't have Node.js already, install the latest "Current" version from the official distribution channel (`https://nodejs.org`), or use your operating system's package manager. If running 64-bit Windows, you may also use the installer from the DVD attatched to this thesis (`ext` folder). It was downloaded from `https://nodejs.org/dist/v6.2.2/`.

   (b) Open the `dist` folder in the command line.

   (c) By default, the server-side part of the application is configured to open `chrome` as the web browser that will handle the client-side. If you want to change that, edit the file `server-options.json` and change the `"browser"` property to a command that will open a different browser of your choice – e.g. `"firefox"`. Save the file.

   (d) Run the command `node server.js`. Before doing that you may optionally update all dependencies to the latest versions by running `npm install`.

   (e) By default the server-side part is configured to run on `127.0.0.1` and uses ports in the range 8079-8082, specified in the `server-options.json` file. Make sure these are available. If not, you may change the defaults again by editing the file.

[1]`https://www.mozilla.org/firefox`
[2]`https://www.google.com/chrome/browser/desktop/`

(f) The project manager view should open in your web browser. You can change the same configuration options as in `server-options.json` here (under "Options").

(g) Click the button "open current path as project" at the bottom.

(h) See 3

2. Alternatively, if you want to just open the editor, open the `editor.html` file from the `dist` folder.

3. A new tab should open in the browser with the editor view. You can start using it as described in Chapter 4.
